## Scan Conversion Algorithms for 2D Output Primitives

- Straight Lines
- Polygons
- Circles
- Ellipses and Other 2-D Curves
- Text (Characters)

## Scan Conversion Algorithms for Drawing Straight Lines

- Task
  - Given pixel coordinates of endpoints P1 (x1,y1) & P2 (x2,y2)
  - Determine which pixels need to be painted
- Criteria
  - Straight as possible
  - Constant density (no gaps or bunching)
  - Density independent of orientation
  - Must be fast

## Line Equations

- Differential equation:  
 $dy/dx = m$  (m=constant--the slope)
- Integrate (indefinite)  
 $y = m*x + \text{constant}$   
 The constant (b) called y intercept  
 (value of y when x=0)
- $y = m*x + b$
- “slope-intercept” form

- Integrate between endpoints (definite)-->  
 $(y2-y1) = m*(x2-x1)$   
 $m = (y2-y1)/(x2-x1)$   
 (an operational definition of slope)
- Integrate between endpoint (x1,y1) and arbitrary point to be plotted (x,y) -->  
 $y - y1 = m*(x-x1)$   
 $y = m*(x-x1) + y1$   
 This is the “point-slope” form

## Parametric Form

Express x and y linearly in terms of a parameter, t

$$x = ax*t + bx$$

$$y = ay*t + by$$

ax, bx, ay, by are constants to be determined

Let t range between endpoints 0 (x1,y1) and 1 (x2,y2)

Determining the constants: Use endpoint values

$$x1 = ax*0 + bx \implies bx = x1$$

$$x2 = ax*1 + bx \implies ax = x2-x1$$

$$\text{So } x = (x2-x1)*t + x1, \quad 0 \leq t \leq 1$$

$$\text{And } y = (y2-y1)*t + y1$$

## Brute Force Line-Drawing Algorithm

Step in x direction (x2>x1)

Compute  $m = (y2-y1)/(x2-x1)$

num-pts = x2-x1+1

x = x1

Repeat num-pts times

$$y = m*(x-x1) + y1$$

SetPixel(round(x),round(y))

x = x+1

Problem if  $|y_2 - y_1| > |x_2 - x_1|$  --> gaps

(1,0) to (6,4)  
 $n = 6 - 1 + 1 = 6$

$x_2 - x_1 = 5$   
 $y_2 - y_1 = 4$   
no gaps!

(1,0) to (3,6)  
 $n = 3 - 1 + 1 = 3$

$x_2 - x_1 = 2$   
 $y_2 - y_1 = 6$   
gaps!

**Solution: Step in y direction**

**Solution: Step in y direction**

If  $|y_2 - y_1| > |x_2 - x_1|$ , step in y  
(assume  $y_2 > y_1$ ):

Compute  $inv\_m = (x_2 - x_1) / (y_2 - y_1)$   
num-pts =  $y_2 - y_1 + 1$   
 $y = y_1$   
Repeat num-pts times

$x = inv\_m * (y - y_1) + x_1$   
SetPixel(round(x), round(y))  
 $y = y + 1$

**Brute Force line algorithm, continued**

Vertical lines ( $x_2 = x_1$ )  
Horizontal lines ( $y_2 = y_1$ )

–Handle as separate cases

**Brute Force Method is Too Slow**

- Each iteration has:
  - floating point multiply
  - floating point add
  - round() operations

**Incremental Methods--The Digital Differential Analyzer (DDA)**

- Idea: get new point from previous point
- $dy/dx = m \implies \Delta y / \Delta x = m \implies \Delta y = m * \Delta x$
- But  $\Delta y = y_{new} - y_{old}$
- And  $\Delta x = x_{new} - x_{old}$ 
  - So  $x_{new} = x_{old} + \Delta x$
  - and  $y_{new} = y_{old} + \Delta y$
  - i.e.,  $y_{new} = y_{old} + m * \Delta x$

**DDA, continued**

- Can choose  $\Delta x = 1$ 
  - stepping in x direction
- Then compute each new y value  
 $y_{new} = y_{old} + m$

### DDA Algorithm (stepping in x, $x_2 > x_1$ )

Compute  $m = (y_2 - y_1) / (x_2 - x_1)$   
 num-pts =  $x_2 - x_1 + 1$   
 $x = x_1$   
 $y = y_1$   
 Repeat num-pts times  
   SetPixel( $x, \text{round}(y)$ )  
 $x = x + 1$   
 $y = y + m$

- As for the Brute force method, if  $|m| > 1$ , we can step in y
- DDA Algorithm (stepping in y,  $y_2 > y_1$ ):  
 Compute  $\text{inv}_m = (x_2 - x_1) / (y_2 - y_1)$   
 num-pts =  $y_2 - y_1 + 1$   
 $x = x_1$   
 $y = y_1$   
 Repeat num-pts times  
   SetPixel( $\text{round}(x), y$ )  
 $y = y + 1$   
 $x = x + \text{inv}_m$

### DDA is Better, but Still Not Fast Enough

- Floating point multiply gone from loop
- But loop still has a floating point add
- And a round()
- WE CAN DO BETTER!
- Best performance:  
 – Only integer adds/subtracts inside loop

### Bresenham's Line-drawing Algorithm

- Used in most graphics packages
- Often implemented in hardware
- Also incremental (new pixel from old)
- Uses only integer operations

- Basic Idea of Bresenham Algorithm:

– All lines can be placed in one of four categories:

- Steep positive slope ( $m > 1$ )
- Gradual positive slope ( $0 < m \leq 1$ )
- Steep negative slope ( $m < -1$ )
- Gradual negative slope ( $0 \geq m \geq -1$ )

– In each case, there are only 2 choices for the next pixel to be plotted!

### The Four Bresenham Cases

- We need a "Predictor" function to choose which pixel is next
- Should use only simple integer math
- Look at Case-A (Steep positive slope)
- Also assume P1 is to the left of P2 ( $x_1 < x_2$ )
  - If not true, points can be swapped
- $\Delta y > \Delta x \implies$  stepping in y

- Assume last pixel plotted (r,s)
  - Next pixel must be at (r,s+1)--"left" pixel
  - or at (r+1,s+1)--"right" pixel
- Mathematical point at (r', s+1)
- Define two horizontal distances
  - dl=distance from math. Pt. to "left" pixel
  - dr=distance from math. Pt. and "right" pixel
  - dl = r'-r
  - dr = r+1-r'

- If  $dl < dr$ ,
  - P1 is closer to actual point than Pr
- I.e., if  $dl - dr < 0$ , choose "left" pixel
- Criterion for choosing P1 is:
  - $dl - dr = r' - r - (r + 1 - r') < 0$
  - or:  $2 * r' - 2 * r - 1 < 0$

Equation for line:

$$y = m * x + b$$

$$\text{define } \Delta y = y_2 - y_1, \Delta x = x_2 - x_1$$

Mathematical point lies on line, so:

$$s+1 = (\Delta y / \Delta x) * r' + b$$

$$r' = (s+1 - b) * \Delta x / \Delta y$$

$$dl - dr = 2 * r' - 2 * r - 1 < 0$$

So:

$$dl - dr = (2 * s * \Delta x + 2 * \Delta x - 2 * b * \Delta x) / \Delta y - 2 * r - 1 < 0$$

If  $dl - dr$  is negative, choose "left" pixel

But this "predictor" is too complex

Multiply by  $\Delta y$

(always positive for Case-A lines)

Call result the "predictor", P

$$P = \Delta y * (dl - dr) = 2 * \Delta x * (s+1 - b) - 2 * r * \Delta y - \Delta y$$

Divide is gone--but it's still too complex

## Bresenham's Contribution

- We're trying to get new point from old point, so:
  - Maybe we can get a new predictor value from its old value in a simple way
  - Need a recurrence relation for P
  - Call P<sub>n</sub> the new value, and P<sub>o</sub> the old value
    - Then  $P_n = P_o + \Delta P$
  - Call s<sub>n</sub> & s<sub>o</sub> the new & old values of s
  - Call m & r<sub>o</sub> the new & old values of r

Change in Predictor:

$$\Delta P = P_n - P_o, \text{ so:}$$

$$P_n = P_o + \Delta P$$

Two cases:

left case (m=r<sub>o</sub> and s<sub>n</sub>=s<sub>o</sub>+1)

right case (r<sub>n</sub>=r<sub>o</sub>+1 and s<sub>n</sub>=s<sub>o</sub>+1)

For both cases:

$$P_o = 2*\Delta x*(s_o+1-b) - 2*r_o*\Delta y - \Delta y$$

Left case:

$$P_n = 2*\Delta x*((s_o+1)+1-b) - 2*r_o*\Delta y - \Delta y$$

$$P_o = 2*\Delta x*(s_o+1-b) - 2*r_o*\Delta y - \Delta y$$

Subtracting P<sub>o</sub> from P<sub>n</sub> gives  $\Delta P$

Result:

$$\Delta P = 2*\Delta x$$

Right case:

$$P_n = 2*\Delta x*((s_o+1)+1-b) - 2*(r_o+1)*\Delta y - \Delta y$$

$$P_o = 2*\Delta x*(s_o+1-b) - 2*r_o*\Delta y - \Delta y$$

Again subtracting P<sub>o</sub> from P<sub>n</sub> gives  $\Delta P$ :

$$\Delta P = 2*(\Delta x - \Delta y)$$

- Both results are very simple (Integers!!)
- Look at current value of the predictor:

If  $P < 0$  // left case

$$P = P + 2*\Delta x$$

$$x = x$$

$$y = y + 1$$

If  $P > 0$  // right case

$$P = P + 2*(\Delta x - \Delta y)$$

$$x = x + 1$$

$$y = y + 1$$

- But to start things off, we need an initial value P<sub>0</sub> of the predictor
- Substitute left-hand endpoint (x<sub>1</sub>,y<sub>1</sub>) into predictor definition:
 
$$P_0 = 2*\Delta x*(y_1+1-b) - 2*x_1*\Delta y - \Delta y$$
- And use fact that (x<sub>1</sub>,y<sub>1</sub>) is on line:
 

i.e.,  $y_1 = (\Delta y/\Delta x)*x_1 + b$

$$P_0 = 2*\Delta x*((\Delta y/\Delta x)*x_1 + b + 1-b) - 2*x_1*\Delta y - \Delta y$$

$$P_0 = 2*\Delta y*x_1 + 2*\Delta x - 2*x_1*\Delta y - \Delta y$$
- Result:
 
$$P_0 = 2*\Delta x - \Delta y$$

## Case-A Bresenham Algorithm

```

If (x1>x2) swap endpoints;
del_x = x2-x1; del_y = y2-y1;
P = 2*del_x - del_y;
cleft = 2*del_x; cright = 2*del_x - 2*del_y;
x = x1; y = y1; num_pts = |del_y| + 1;
Repeat num_pts times
  SetPixel(x,y); y = y + 1;
  If (P < 0)
    P = P + cleft;
  Else
    {P = P + cright; x = x + 1;}
  
```

- Can be generalized to handle Case-C (steep negative slope) lines
- Compute  $sd_y = \text{sign}(\Delta y)$ 
  - = 1 if  $y_2 > y_1$
  - = -1 if not
- Then, in definition of P and  $crigt$ :
  - Replace  $\Delta y$  with  $sd_y * \Delta y$
  - Replace  $y = y + 1$  with  $y = y + sd_y$
- Then both Case-A and Case-C lines are handled

## More Info on Bresenham Line-drawing Algorithm

- See Hearn & Baker Text Book
- Section 3-1 (pages 88-95)
- Specifically Case-B lines

## Speeding Up Bresenham

- Bresenham's algorithm calls `SetPixel()`
- Not optimized
  - `SetPixel(x,y)` must work for any pixel
  - For  $W \times H$  screen,  $\text{Address} = W * y + x$
  - Multiply involved
- Bresenham: We know next pixel is one of two choices
- Faster to access frame buffer with addresses

- Assume Row major order
- Take advantage of symmetry
- Store addresses instead of  $(x,y)$
- Example:  $W \times H \times 256$ 
  - $\text{Address} = W * y + x$
  - Look at Case A (gradual +m)
- Only integer add needed

## Case A Line (gradual +m)
